Abstract
Acanthamoeba keratitis (AK) is a sight threatening infection caused by the free-living amoeba Acanthamoeba. This infection is largely associated with contact lens wear and the recent increase in AK incidences highlights the ineffectiveness of existing curative and preventative treatments. Current curative and protective treatments being active in part, only against the infective trophozoites and often inducing their conversion to the protective cysts is a major issue, particularly when the latter are the main cause of disease resurgences and relapses. These point to the need for the discovery of new drugs for curative and preventive treatments. Two structurally similar chemical classes, alkylphosphocholines (APCs) and quaternary ammonium compounds (QACs) that address these issues will be discussed in this review.

Introduction
Acanthamoeba are free-living single celled eukaryotes, existing in two forms; an infective trophozoite and a dormant cyst. They are ubiquitously found in both natural and man-made environments and are of clinical relevance due to their opportunistic parasitic activities in humans1. There are several Acanthamoeba associated infections in humans, but this review will focus on the sight threatening disease of the eye Acanthamoeba keratitis (AK)2 and the use of two promising compounds as curative and preventive treatments that will validate its incorporation into contact lens solutions. Curative treatment is the use of systemic oral drugs and topical eye drops while preventive treatment employs medical devices e.g. contact lens solutions to sterilise contaminated lenses and prevent contact lens to eye transmission.

AK is largely associated with improper contact lens hygiene and the limited activity of contact lens solutions against Acanthamoeba. The attachment of Acanthamoeba to contact lenses allows transmission to, and infection of the cornea arising from the feeding activities of trophozoites in the eye3. Incidence rates of AK have been increasing globally since the start of the 21st century. On average, the annual number of AK cases within the Moorfields eye hospital, England increased from 12.8 to 48.6 between 2000-2008 and 2009-20164, and 16 to 49 in the Netherlands between 2009 and 20155. Similar reports are documented in Australia and the USA with rising incidences, the Sydney Eye Hospital reported the annual average cases of AK to be 2.6 and 3.6 before and after 20076, while cases in Iowa, USA increased in average annual cases from 2.9 to 6.5 between 2002-2009 and 2010-2017 respectively7. The reasons for this spatio-temporal increase are not readily apparent but improved diagnostic
techniques and ineffective contact lens cleansing solutions are thought to be key factors 4.

Existing curative and preventive treatments for AK mainly target trophozoites but become inactive if they induce their conversion to cysts via the process of encystation. The cellulose cell walls of cysts protect the parasite against drug activity and the reduction of drug concentrations in the eye to sub-lethal levels initiates the reversion of cysts to the trophozoite stage, ultimately leading to disease resurgence.

The inability of current topical and oral drugs and many widely used contact lens solutions to produce death at low concentrations against cysts, the requirement of a prolonged treatment regime to ensure complete clearance from the eye and the ability to induce encystation are factors that have made AK treatment and prevention difficult. In some instances, frequent application of drugs topically for up to a year is required, causing corneal damage and very often patients require surgical intervention e.g. corneal transplant to repair the damaged cornea. Preventive protocols with commonly used contact lens solutions such as one-step hydrogen peroxide solutions are similarly ineffective with even compliant users at risk.

Two structurally similar compounds named alkylphosphocholines (APCs) and quaternary ammonium compounds (QACs) have received attention for their activity against several protozoan pathogens, including Acanthamoeba spp. These compounds are active against cysts and synergistic with other antimicrobials including Acanthamoeba keratitis. Work by Walochnik and colleagues on their anti-amoebic properties for combating Acanthamoeba keratitis concluded that APCs are promising drug candidates that might prove useful against AK. This minireview provides an update and the state of the art of this chemical class and an analogue called QACs, extensively used as preventative strategy against AK.

Alkylphosphocholines against Acanthamoeba Keratitis

Structure of alkylphosphocholines

APCs are zwitterionic molecules comprised of a head made from a trimethylamine moiety containing a positively charged nitrogen atom and joined by a two alkyl-carbon linker to a negatively charged phosphoryl group. The tail, made of varied number of alkyl-carbons, is attached to the phosphoryl group (Figure 1).

Figure 1: General structure of an alkylphosphocholine. The molecule is comprised of a negatively charged phosphoryl group and positively charged nitrogen joined by a linker made from two alkyl-carbons which forms a neutral charged head group. The tail is comprised of varied length of alkyl-carbon chain with different degree of unsaturation and can be with sulphur and oxygen substitutions for the hydrogen joined to the phosphoryl moiety. “n” indicates the variable alkyl-carbon tail.

Activity of oral miltefosine against Acanthamoeba keratitis

The APC, miltefosine was first developed as an anti-cancer drug but was subsequently shown to have anti-fungal and anti/protozoal properties. Systemic use of miltefosine was licensed in the USA as a treatment of AK in 2016 and when incorporated into treatment regimens at 50mg/ml given three times daily (TD) for up to two months has proved to be an effective oral systemic treatment against Acanthamoeba mainly in combination. The use of miltefosine solely as an oral administration is yet to be tested, but in combination with topical applications e.g. chlorhexidine (0.06%) and propamidine (0.1%) has demonstrated success. Hirabayashi et al. reported the use of miltefosine in the treatment of a patient suffering with progressively worsening AK. For this 17yr old female patient, earlier treatments with topical polyhexamethylene biguanide (PHMB, 0.02%), chlorhexidine (0.02%), moxifloxacin (0.5%), cyclopentolate (1%) and oral administration of both 500mg valacyclovir and 200mg voriconazole twice daily (BD) were unsuccessful. The addition of miltefosine (50mg, TD, orally) in particularly with topical chlorhexidine (0.06%) and propamidine isethionate (0.1%) for five weeks reduced the infection and accompanying symptoms, pain improved conjunctival injection and corneal opacity were reduced and improved respectively. No resurgence was observed one-year post treatment. Similar results have been described by Dewan et al., again a 44yr old female who did not respond to treatment with topical chlorhexidine (0.02%), PHMB (0.02%), gatifloxacin (0.3%) and voriconazole (0.5mg/ml) and oral voriconazole (200mg, BD) was responsive to oral miltefosine (50mg, TD) after 11 months of treatment. Resurgence was not evident thirty-month post treatment. The efficacy of miltefosine is reproducible and has been replicated in part by Naranjo et

al. Oral miltefosine (50mg, TD) was effective and reduced parasite load in the eye of the patient after three weeks, with no re-infection noted (Table 1). However, in four out of six cases, inflammatory responses produced either by the eye immunity towards the killed Acanthamoeba or the immunomodulatory effect of miltefosine produced deterioration in the eye which was corrected by penetrating keratoplasty. Studies of the combination of this compound with anti-inflammatory medication is required to determine if managing the immune response could improve treatment, although it has been suggested that miltefosine might be used as an immune modulating anti-inflammatory compound so an extensive investigation of this inflammatory effect would be required.

Miltefosine is yet to be licensed for AK treatment in the UK, but clinical trials to prevent trophozoites migration from the eye to the central nervous system, resulting in granulomatous amoebic encephalitis (GAE), an infection with a mortality rate of 90%, has proven successful. Preliminary results based on histopathological analysis showed that while migration was halted, the infection was not cleared from the eye. However, treatment with miltefosine was only administered for two-weeks prior to surgery. These results show that the treatment of AK is complicated and marred with issues of toxicity and dosage regime (Table 1) but confirms that miltefosine is a bona fide treatment for AK in combination with the standard topical treatments particularly when they are ineffective.

Activity of topical miltefosine against Acanthamoeba keratitis

The success of oral miltefosine suggests that it can be absorbed easily by the gut, is able to survive the first pass effect in the liver and the bioavailability in the eye is of sufficient concentration to cause Acanthamoeba death. This suggests that lower doses would be sufficient for topical use. Work done by Polat et al. demonstrated that the topical application of miltefosine alone to the Acathamoeba-infected eyes of Syrian hamsters for 28 days at 160μM cleared AK infections by 85% (Table 2). In contrast, the current recommended topical treatment combinations of 0.1% propamidine isetionate and 0.02% PHMB was less effective in the eyes of Syrian hamsters than miltefosine alone. The same group reported further benefits for the use of miltefosine as a combined topical treatment against Acanthamoeba keratitis in rats. Miltefosine (160μM) combined with PHMB (0.02%) or chlorhexidine (0.02%) but not propamidine isethionate (0.1%) showed synergistic activity (Table 2). This study illustrated that existing topical treatments with PHMB can be improved by the addition of topical miltefosine. We thus propose that miltefosine should be integrated with current treatment regimens for improved prognosis for patients.

In vitro activity of APCs against Acanthamoeba

There are several in vitro studies describing the efficacy of APC analogues against Acanthamoeba with most showing miltefosine (hexadecylphosphocholine) to have optimal activity against Acanthamoeba trophozoites (Table 3). In a structure activity relationship study undertaken by Mooney and colleagues, a series of APCs with different alkyl-carbon chain length ranging from 8-18 carbons, demonstrated that miltefosine was cytotoxic at 46μM and cytostatic below this dosage against trophozoites. Another study showed that 39mM to 78mM of miltefosine was toxic to cysts. Similar results reported elsewhere for miltefosine have shown that the activity of miltefosine against Acanthamoeba is influenced by the life form, the Acanthamoeba species, the strain, and the duration of the drug in contact with the protist. Nevertheless, they have shown that approximately 3000-fold lower concentrations of miltefosine was required for in vitro treatment than for topical and oral application.

Quaternary Ammonium Compounds Against Acanthamoeba

Structure and classification of quaternary ammonium compounds

QACs lack the negatively charged phosphoryl group of APCs resulting in a net positive charge. They are cationic molecules containing a positively charged central nitrogen atom attached to four substituents. Attachments to aliphatic and aromatic functional groups have produced two main types of QACs. In this review, they will be referred to as benzylated and non-benzylated if the compound contains an aromatic benzyl ring (e.g. benzalkonium chloride and benzethonium chloride) or lacks one (e.g. tetraethylammonium bromide and dodecyltrimethylammonium bromide) attached to the nitrogen atom respectively. This makes a good case for their incorporation into contact lens solutions as a preventive strategy. Studies show that human tissues such as the eye, organotypic skin models and mammalian breast cancer cells are refractory to miltefosine concentrations 160μM, 50μM and 150mM respectively, which suggest that it could be safe to use as a preventive strategy and eye toxicity would not be an issue.

Activity of quaternary ammonium compounds against Acanthamoeba

Broad antimicrobial properties against virus, bacteria and protozoans have been reported in 1,866 studies since 2015. The activity of both QACs against Acanthamoeba has also been reported recently. Benzylated QACs such as benzalkonium chloride (BAC) have widespread clinical applications, commonly used in ophthalmic

<td>Hexadecyl-PC (Miltefosine), octadeyl-PC, elaidyl-PC, eru- cyl-PC, edelfosine</td>
<td>Trophozoites of A. castellanii, A. polyphaga incubated with miltefosine at concentrations ranging from 7.8-1000μM for 96 hours.</td>
<td>Findings: The order of activity against Acanthamoeba spp. was Hexadecyl-PC &gt; octadecyl-PC albeit with A. castellanii more susceptible than A. polyphaga. MIC for hexadecyl-PC was 62.5μM and 125μM for A. castellanii and A. polyphaga respectively. Conclusion: Species-specific activity of miltefosine against Acanthamoeba was highlighted, vital to inform a preventative strategy.</td>

<tr>
<td>nbQAC:</td>
<td>Benzalkonium chloride (BAC)</td>
<td>Trophozoites and cysts of A. castellanii, A. polyphaga treated with BAC at concentrations ranging from 2.7-134μM (0.005-0.02%) for 48 hours in the BAC containing solutions Levofloxacin (Oftaquix; 0.005% BAC), trifluorothymidine ( 0.02% BAC)</td>
<td>Findings: BAC monotherapy was effective in killing trophozoites at concentrations of 0.02μM and 0.005μM and cysts at concentrations of 0.04μM and 0.02μM for A.castellanii and A.polyphaga respectively. The Levofloxacin (Oftaquix) ophthalmic solution with 0.005% BAC has a minimal amoebicidal concentration of 156μg/ml and 312μg/ml and cysticidal concentration of 625μg/ml and 625μg/ml for A.castellanii and A. polyphaga respectively. For TMT containing 0.02% BAC these same respective concentrations were 625μg/ml and 1250μg/ml for trophozoites and 5000μg/ml and 2500μg/ml for cysts. Conclusion: BAC is highly potent to Acanthamoeba trophozoites and cysts and addition to contact lens solutions significantly increases efficacy.</td>

solutions as topical and preventive strategies, and can cause death at concentrations ranging from 2.69μM to 20.97M and 20.97μM to 41.93μM against trophozoites and cysts respectively, far lower than that in ophthalmic solutions being 107.52μM. Lower concentrations of benzylated QACs formulated in medical devices with longer incubation times in cytotoxicity assays have increased efficacy. Membrane to produce shock due to the opposing charge can rapidly reverse the net negative charge of the plasma membrane to produce cell death. Therefore, benzylated QACs can be used as a preventative strategy for Acanthamoeba Keratitis.

### Findings
- Benzylated QACs in Transoak were most effective and killed cysts from all species and strains within four hours. Lower BAC concentrations present in Duracare (0.004%) and Transol (0.004%) required more than eight hours to produce similar activity against cysts. Optifree and Optisoak containing Polyquad-1 had no cysticidal activity for all Acanthamoeba species and strain.
- Benzylated QACs as a medical device demonstrated better activity against Acanthamoeba trophozoites and cysts than their non-benzylated counterpart.

### Conclusion
The impact of APCs in AK treatments, even amongst the ‘difficult to treat’ immuno-suppressed patients is promising. Despite the clinically observed effect, little has been published on the topic of benzylated QACs. Further research is needed to better understand their efficacy and safety in clinical trials.

### Findings
- Octadecyl-TMAB and miltefosine (hexadecyl-PC) were most effective QAC and APCs against Acanthamoeba trophozoites respectively, with the nbQACs, Octadecyl-TMAB cytotoxic at low concentrations and demonstrated cysticidal activity after 24 hours. Dodecyl-TMAB and miltefosine was synergistic.
- nbQACs more effective than APCs and demonstrated higher cysticidal activity but synergistic when combined.

### Conclusion
QACs are more effective against Acanthamoeba trophozoites than APCs.

Key: bQAC – benzylated QAC, nbQAC – non-benzylated QAC, -TMAB – trimethyl ammonium bromide, -PC - Phosphocholine
is known about its clinical pharmacodynamics, mainly because good quantitative markers of parasite load and treatment response are not available for AK. Disease-specific pharmacokinetics for miltefosine alone\textsuperscript{53} and in combination\textsuperscript{54} are available for other anti-parasitic infections e.g. Leishmaniasis but are yet to be available for AK. Further clinical research is required for these compounds use against AK. The studies highlighted in this review suggest that miltefosine may reduce current disease resurgence, common with current curative and preventative treatments. Similarly, pharmacodynamics and pharmacokinetic for QACs are scarce and are perhaps hampered by their extensive use as preservatives. The strong efficacy of QACs against \textit{Acanthamoeba} is a framework for development as a treatment or preventative for AK, if corneal toxicity issues are addressed.
